## ABSTRACT

Pure TiO<sub>2</sub> and Cr doped TiO<sub>2</sub> (0.1-1.0wt% Cr) nanoparticles were synthesized via sol gel method. This study focuses on narrowing the TiO<sub>2</sub> band gap energies in order to enhance the photocatalytic efficiency under visible light. The synthesized samples were characterized by X-Ray diffraction method (XRD), field emission (FESEM) and also UV-Vis diffuse reflectance spectroscopy (DRS). The photocatalytic activity under sunlight irradiation was demonstrated by photocatalytic decomposition of methylene blue in water using UV/Vis spectrophotometer. The XRD analysis of pure TiO<sub>2</sub> and doped TiO<sub>2</sub> calcined at 500°C showed a mixture of anatase and rutile phases with decreasing crystallites size from 13.3nm to 11.6nm as the concentration of Cr was increased. The anatase-rutile phase transformation increased from 28.8% to 57.4%. An indication shows that at 0.75wt%, Cr the anatase and rutile phases have equal composition percentage. This study demonstrated that band gap energy of TiO<sub>2</sub> was reduced with Cr doping which could enhance the photocatalytic efficiency. Sample containing 1.0wt% exhibit the lowest optical band gap energy at 2.86 eV. The optimum chromium doping concentration was found to be at 0.1 wt% Cr corresponding to band gap energy of 2.87 eV and degradation rate of 84%.

**Keywords:** *Sol-gel chemistry, optical properties, titanium dioxide, chromium; photocatalytic activity*

## INTRODUCTION

Numerous organic compounds that are commonly used in industrial, agricultural, and domestic fields cause contamination to the environment. This frequent occurrence has received great attention on the investigation of photocatalysis to eliminate hazardous substances. In the preceding years photocatalytic technology has revealed to be a promising method to solve the environmental crisis since it is an economical and harmless technology [1-4]. Titanium dioxide is known as an efficient photocatalyst. It has received enormous interest due to it being inexpensive, non-toxic, and biocompatible that shows high photoefficiency and activity besides the capability to degrade gaseous and aqueous contaminants and hence is a good candidate for use in air clean-up and water purification [5-8].

However, titanium dioxide has a number of limitations in that the high energy band gap (ca. 3.0 eV for rutile and 3.2 eV for anatase) make it only possible to be activated by ultraviolet (UV) light [9, 10]. Modifications of titanium dioxide appeared necessary to improve the performance of the photocatalytic by doping with several metal ions in order to extend the absorption range of  $\text{TiO}_2$  into the visible region. In fact, previous studies had proven that doping with transition metal ions resulted in improved performance of photocatalytic activity. Where these transitions metal ions such as  $\text{Fe}^{3+}$ ,  $\text{Y}^{3+}$  and  $\text{Mn}^{2+}$  helped to boost the photocatalytic activity by trapping photo-generated electrons in  $\text{TiO}_2$  or due to the genesis of reactive complexes that lifted the electron-hole pair lifetimes [11-13].

In this work, the photocatalytic activity in visible light of  $\text{TiO}_2$  doped with varying amount of Cr were synthesized in alkaline medium and the optical property been studied. Herein, in this study we report on the synthesis of sol-gel  $\text{TiO}_2$  with Cr metal ions where the photocatalytic will be done by using sunlight as the energy light source to improve the performance of the photocatalytic activity. To our knowledge, the effect of Cr as dopant for the photocatalytic activity of  $\text{TiO}_2$  under direct sunlight excitation was not reported elsewhere. The few published data were concerned only with

photocatalytic activity under UV irradiation and visible light with various results depending on the type of dopant and preparation method.

## EXPERIMENTAL

### Sample Preparation

Chromium doped titania with increasing amount of chromium (0.1-1.0 wt%) were synthesized via sol gel method. The method was adopted with modification from Hong-bin Yang et al [14]. Absolute ethyl alcohol was mixed with titanium butoxide ( $\text{Ti}(\text{OBU})_4$ ) with a ratio of 5:2. The triethanolamine was added into the solution and constantly stirred for 15 minutes using an electromagnetic stirrer. Then, absolute ethyl alcohol and distilled water were added into the above solution with stirring. An increasing amounts of 0.1, 0.5 and 1.0 wt % of  $\text{Cr}^{3+}$  was added into a series of the above solutions. Stirring was continued for half an hour, stabilized and aged for 3 days at room temperature to form gel. The gel was dried at  $80^\circ\text{C}$  for 72 h, ground and calcined at  $500^\circ\text{C}$  for 4 h.

### Characterisation

The analysis was performed using XRD spectrometer model Panalytical X'Pert PRO. The diffractometer data were recorded for  $2\Theta$  values in a range of  $10^\circ$  to  $80^\circ$ . The patterns were compared with JCPDS reference data for phase identification and crystallite size was calculated using Scherrer equation by referring the 2 most intense peaks of 101 and 110 show on the XRD diagram. The microstructure of the catalyst powder was determined by high resolution scanning electron microscopy (FESEM) model Carl Zeiss SMT, SUPRA'40 VP. UV-Vis NIR diffuse reflectance spectroscopy (DRS) was performed with a Shimadzu Cary 5000 UV-Vis-NIR spectrophotometer equipped with an integrating sphere to identify the optical band gap energy. The absorption edge value and the band gap energy can be computed based on the reflectance spectra. Photocatalytic activity of the  $\text{Cr}^{3+}$  doped catalyst was evaluated by measuring the intensity degradation of methylene blue aqueous solution under sunlight irradiation. The methylene blue (MB) was used as a model compound. In the experiment 0.1 g of the prepared catalyst powder with increasing  $\text{Cr}^{3+}$  doping was dispersed into a 50 ml of 10 ppm methylene blue solution with 10ppm concentration. This solution was

magnetically stirred in the dark for 30 minutes before exposure to sunlight to establish the adsorption-desorption equilibrium of the organic dye. The study was carried out under direct sunlight between 11 am and 2 pm with the average solar intensity at 500-600 W/m<sup>2</sup> which was measured by SEAWARD Solar Survey 100. The experiment was performed on the bright sunny day with temperature 32°C. The first MB sample was taken at the end of the dark adsorption period just before the light was turned on and was treated as the starting point ( $t = 0$ ). Aliquot samples were then withdrawn regularly at 30 minutes interval up to 180 minutes. The photocatalytic degradation reaction was determined by measuring the absorbance of the solution samples with UV-Vis spectrophotometer at  $\lambda_{\text{max}}$  of MB (622 nm). The photocatalytic degradation of MB was calculated from the following relationship:

$$\text{Degradation percent, } D\% = [(A_0 - A_t) / A_0] \times 100\%$$

Where  $A_0$  is the initial absorbance of MB solution and  $A_t$  is the absorbance of MB solution at time  $t$  (minutes).

## RESULTS AND DISCUSSION

### Phase Analysis

Representatives the X-ray diffraction pattern of pure TiO<sub>2</sub> as dried at 80°C for 72 h and calcined at 500°C for 4 hours (h) and chromium doped TiO<sub>2</sub> photocatalyst calcined at 500°C for 4h are shown in Figure 1. The as dried TiO<sub>2</sub> powder in Figure 1 is amorphous but crystallized to form rutile and anatase after 4h heat treatment at 500°C. As can be seen, for all the samples appears in two polymorphic forms which are anatase and rutile. This results corroborate well with previous studies where Bouattour et al. also observed similar effect using Li<sup>+</sup> and Rb<sup>+</sup> as dopants [15]. However, anatase and rutile intensity changed when the dopant concentration changed. According to Figure 1, it can be seen at 0.5 and 1.0 wt% Cr the rutile intensity is also increased. However, at 0.1wt% Cr the anatase phase intensity is increased while the rutile phase intensity is decreased compared to the pure TiO<sub>2</sub>. 0.5wt% Cr and 1.0wt% Cr. Contrary to our previous work on cerium doping, the addition of chromium fallouts into a reduction intensity peaks on the anatase phase [16]. At the prominent peak of 38.04° the intensity of

anatase phase is decreased at 0.5wt% and 1.0wt% Cr dopant concentration. It could be inferred that the increase concentration of chromium caused anatase poorly crystallized. Based on the reference of anatase and rutile phases of  $\text{TiO}_2$  (JCPDS 711166, 731765) the synthesized photocatalysts correspond to tetragonal crystal system having space group of I41/amd and P42/mnm respectively. Based on Figure 1, the XRD peaks broaden when the chromium concentration is at 0.5wt% and 1.0wt%. This could be inferred to the crystallization of anatase nanopowders diminished and accompanied by a decrease in the crystallite size of Cr doped  $\text{TiO}_2$ . This can be proven by the result displayed in Table 1 where the crystallite sizes of the anatase phase are reduced from 13.3 nm for pure  $\text{TiO}_2$  to 12.1nm and 11.6 nm for the dopant concentration at 0.5wt% Cr and 1.0wt% Cr respectively. Peng et al believed that the reduction in grain size could be ascribed to the existence of Cr-O-Ti, which hindered the coalescence of the neighboring grains suppressing the growth of anatase rutile crystals throughout the heat treatment process [17]. This is dissimilar to that of 0.1wt% Cr where the crystallite size is 13.5 nm which is 0.2 nm greater than pure  $\text{TiO}_2$ .

Figure 1: XRD patterns of pure TiO<sub>2</sub> and Cr-doped TiO<sub>2</sub>

Table 1: Anatase-Rutile composition and crystallite size of pure TiO<sub>2</sub> and Cr-doped TiO<sub>2</sub>

Samples	Anatase X <sub>A</sub> %	Rutile X <sub>R</sub> %	Ratio X <sub>A</sub> %/X <sub>R</sub> %	Crystallite size (nm)
TiO <sub>2</sub>	71.8	28.2	2.55	13.3
0.1wt% Cr/ TiO <sub>2</sub>	73.9	26.1	2.83	13.5
0.5wt% Cr/ TiO <sub>2</sub>	57.1	42.9	1.33	12.1
1.0wt% Cr/ TiO <sub>2</sub>	42.6	57.4	0.74	11.6

The mass fraction of rutile in Figure 2 was calculated based on the formula developed by Spurr and Myers [18]. Pure TiO<sub>2</sub> consists of 28.2% of rutile phase while at 0.1 wt% Cr, 0.5wt% Cr and 1.0wt% Cr the percentage of rutile phase is at 26.1%, 42.9% and 57.4% respectively. The rutile percentage is decreased at 0.1wt% Cr but the rutile percentage is increased at 0.5wt% and 1.0wt% Cr. This percentage composition of rutile phase elucidating that at higher Cr doping did not inhibit the formation of rutile phase and stabilize the anatase phase at 500°C calcined temperature. It is

noted at 0.75wt% Cr doping resulted in 50:50 of anatase and rutile phase which is shown at intersection point depicted in Figure 2.

Figure 2: Proportion of anatase and rutile of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$

## MICROSTRUCTURAL ANALYSIS

Figure 3 shows the FESEM micrographs of the pure  $\text{TiO}_2$  and Cr doped  $\text{TiO}_2$  nanopowders. The microstructure of pure  $\text{TiO}_2$  nano powders consists of large spherical particles. However, the morphology of chromium doped  $\text{TiO}_2$  nanopowders show that conjugated spherical particles become smaller as the Cr concentration increased.

**Figure 3: FESEM of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$**

## OPTICAL PROPERTIES

The diffused reflectance spectra in the Cr doped  $\text{TiO}_2$  powders are supplemented by the colour change in from white, to yellow to dark green when the  $\text{Cr}^{3+}$  concentration increased. The corresponding diffused reflectance spectra are shown in Figure 4. The diffused reflectance spectra shift towards longer wavelength as Cr concentration increased. The absorption spectra  $F(R)$  were computed by adopting the Kubelka-Munk equation,  $F(R) = (1 - R)^2/2R$  where  $R$  is the diffused reflectance of the samples [19].

Figure 4: Diffuse reflectance spectra of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$

Figure 5: Kubelka-Munk absorption curves of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$

The corresponding Kubelka-Munk absorption curves of pure TiO<sub>2</sub>, 0.1wt% Cr, 0.5wt% Cr and 1.0wt% Cr are illustrated in Figure 5. It is demonstrated in the absorption spectra that pure TiO<sub>2</sub> depicts one only absorption peak near to 350 nm. On the other hand, Cr doped TiO<sub>2</sub> samples exhibit an absorption peak around 350 nm and one broad peak in the range of 400 and 600 nm. The peak at 350 nm occurred because of the phonon assisted indirect transition from the edge to the center of Brillouin zone [20]. While the broad peak at 400-600 nm is due to <sup>4</sup>A<sub>2</sub> (F) to <sup>4</sup>T<sub>1</sub> (F) transition. The other peak is in the range of 600–800 nm wavelength occurred due to spin forbidden <sup>4</sup>A<sub>2</sub> (F) to <sup>2</sup>E, <sup>2</sup>T<sub>1</sub> transition. Chromium ions were claimed to show these types of d–d electronic transition when it is in +3 oxidation states, under the influence of octahedral crystal field. In anatase TiO<sub>2</sub>, Ti<sup>4+</sup> is surrounded by six oxygen ions forming TiO<sub>6</sub><sup>2-</sup> octahedra. When Cr<sup>3+</sup> occupies Ti<sup>4+</sup> in the lattice, it may form CrO<sub>6</sub>. In that condition, it is under the ligand field environment of six O<sup>2-</sup> ions. Due to the repulsion between the electrons present in Cr<sup>3+</sup> and O<sup>2-</sup> ion, the energy of d orbital is splitted up giving ground state <sup>4</sup>A<sub>2</sub> and excited states <sup>4</sup>T<sub>1</sub>, <sup>4</sup>T<sub>2</sub>, <sup>2</sup>E. Absorption of UV–vis light excites the electrons from ground state to different excited states giving aforementioned d–d absorption peaks. The d–d transition of Cr<sup>3+</sup> in TiO<sub>2</sub> is shown in the inset of Figure 5 [21]. Hence for further conformation, the optical band gap energy was determined by extrapolation of the tangent to the inflexion point between the absorption tail and the band states where  $\alpha = 0$  from the Tauc plot in Figure 6. The Tauc plot was applied based on the Tauc relation using the following equation:

$$\alpha = A(h\nu - E_g)^n / h\nu,$$

Where  $\alpha$  is absorption coefficient, A is constant,  $h\nu$  is the energy of light and n is a constant depending on the nature of the electron transition modes ( $n = 1/2$  for direct allowed transitions)[22, 23]. The reduction in the band gap energy can be observed as the chromium impurities been added. The bare TiO<sub>2</sub> energy band gap was found to be at 2.97 eV. This value is relatively lower from the bulk TiO<sub>2</sub>; (Anatase  $E_g = 3.2$  eV, Rutile  $E_g = 3.0$  eV). While 2.87 eV, 2.91 eV and 2.86 eV for 0.1, 0.5 and 1.0 wt% Cr respectively. This can be understood sample at 1.0wt% Cr containing highest rutile phase (Table 1) has lowest band energy because rutile band gap energy is lower than anatase band gap energy. Previous study reported that distortion in energy band contribute in alteration of the absorbance spectral characteristic[24].

Figure 6: Tauc plot of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$

## PHOTOCATALYTIC ACTIVITY

Figure 7 shows the degradation of methylene blue against irradiation time in the presence of the sunlight irradiation. The performance of the photocatalytic activity increased when the composition of anatase phase is greater than the rutile phase. The percentage of the reduction of methylene blue are 41%, 84%, 72%, 70% for pure  $\text{TiO}_2$ , 0.1wt% Cr/ $\text{TiO}_2$ , 0.5wt% Cr/ $\text{TiO}_2$  and 1.0wt% Cr/ $\text{TiO}_2$  respectively. Based on Figure 6, Cr doping shows a significant influence on the certain properties of the  $\text{TiO}_2$ . Whereby Cr doped  $\text{TiO}_2$  upon an increasing Cr concentration were investigated throughout the following characteristics: (i) the anatase-to-rutile transformation, (ii) decrease of the rutile crystallite size, (iii) increase of visible light absorption and finally, (iv) photocatalytic efficiency. This can be explained by an improved visible light absorption which may allow an improved charge carrier separation in the synthesized samples of Cr doped  $\text{TiO}_2$  and acting as electron traps. However, the decrease of the photocatalytic performance for higher Cr loading can be explained by an improved charge carrier

recombination due to a high defect concentration, small rutile crystallite size and low anatase content [28]. As can be observed in Figure 7, 0.1wt% shows the best performance photocatalytic activity because of higher anatase content compared to pure  $\text{TiO}_2$ , 0.5wt% and 1.0wt% Cr doped  $\text{TiO}_2$ . This indicated that 0.1% Cr doped  $\text{TiO}_2$  is an optimal doping level for photocatalysis under visible sunlight. The crystallite size of anatase phase also show 0.1wt% is the largest compared to pure  $\text{TiO}_2$ , 0.5wt% Cr and 1.0wt% Cr. This is in a good agreement which anatase has been known as a photoactive phase.

Figure 7: Degradation of methylene blue of pure  $\text{TiO}_2$  and Cr-doped  $\text{TiO}_2$

## CONCLUSION

Pure  $\text{TiO}_2$  and chromium doped  $\text{TiO}_2$  were synthesized via sol-gel route ranging from 0.1 - 1.0 wt% Cr. The XRD analysis of pure  $\text{TiO}_2$  and doped  $\text{TiO}_2$  calcined at  $500^\circ\text{C}$  showed a mixture of anatase and rutile phases with decreasing crystallites size as the concentration of Cr was increased. This study demonstrated that energy band gap of  $\text{TiO}_2$  was reduced with Cr doping which could enhance the photocatalytic efficiency. The optimum

chromium doping concentration after synchronizing the experimental data with that of theoretical data was found to be 0.1 wt% corresponding to band gap energy of 2.87 eV and degradation rate of 84%.

## ACKNOWLEDGEMENT

The authors are gratefully thanks to Ministry of Education (MOE) for supporting this research under the RAGS grant (600-RMI/RAGS 5/3 (26/2012)), and Universiti Teknologi MARA (UiTM) for the facilities provided in succeeding this research.
